Abstract: We evaluated the movement in the daily number of COVID-19 cases in response to the real GDP during the COVID-19 pandemic in Thailand from Q1 2020 to Q1 2021. The aim of the study was to find the number of COVID-19 cases that could maintain circulation of the country's economy. This is the question that most of the world's economies have been facing and trying to figure out. Our theoretical model introduced dynamic stochastic general equilibrium (DSGE) models with a special emphasis on Bayesian inference. From the results of the study, it was found that the most reasonable number of COVID-19 cases that still maintains circulation of the country's economy is about 3000 per month or about 9000 per quarter. This demonstrates that the daily number of COVID-19 cases significantly affects the growth of Thailand's real GDP. Economists and policymakers can use the results of empirical studies to come up with guidelines or policies that can be implemented to reduce the number of infections to satisfactory levels in order to avoid Thailand lockdown. Although the COVID-19 outbreak can be suppressed through lockdown, the country cannot be locked down all the time.

Keywords: Bayesian; DSGE; COVID-19; Thailand's economy circulation; number of coronavirus disease 2019 cases; the optimal number of COVID-19 cases

1. Introduction

The global outbreak of the COVID-19 pandemic has affected all countries in terms of economy, politics, and society. [McKibbin and Fernando \(2020\)](#) stated that the COVID-19 global pandemic has caused significant global economic and social disruption. Thailand has also been affected by the COVID-19 pandemic just as the world is experiencing. The spread of COVID-19 in Thailand can be divided into three waves until now. The first wave of the epidemic occurred in early 2020, the second wave started in late 2020, and the latest wave, or the third wave, started in late March or early April 2021.

The first wave of the outbreak of Thailand started at the beginning of last year. During January 2020, Thailand began to have foreign screening measures at Bangkok's Suvarnabhumi Airport. As a result of screening measures, Thailand found the first case of COVID-19 in the country. After finding the first confirmed cases of COVID-19, the Department of Disease Control has continued to monitor and screen passengers on planes. It has also closely and continuously monitored the situation of patients in foreign countries. After Thailand had started screening a number of patients, the Department of Disease Control and the Ministry of Public Health upgraded the emergency operations center to level 2 and level 3, respectively. The aim of raising the level of the emergency system was to

closely monitor the situation of the disease both at home and abroad (source: Department of Disease Control, Ministry of Public Health). Soon after, the country experienced a new round of cluster outbreaks in public places such as entertainment venues, boxing stadiums, and religious ceremonies despite Thailand's strict tourist screening measures. This has led the country to carry out more stringent action such as lockdown measures in areas that are at risk of spreading the COVID-19 epidemic. Although Thailand is willing to use the economic damage from lockdowns as the cost to try to bring the number of infections in the country to zero for almost a year, a new wave of outbreaks has emerged.

A new wave of cases of the outbreak following the lockdown in the country occurred on 17 December 2020 at the Central Shrimp Market in Samut Sakhon province. This round of COVID-19 outbreaks was considered to be the second round of outbreaks in Thailand. In this wave, the infection was detected from foreign workers who came to work at the Central Shrimp Market. As this outbreak came from a group of workers, the infection spread rapidly due to a large concentration of labor in the area. From the cases of infected people in Samut Sakhon province, this time, the number of new cases in Thailand were found to be 576. Therefore, the Ministry of Public Health issued measures for control, involving carrying out space lockdown measures together with screening measures and proactive examination in various places. It is hoped that Thailand will be able to control the spread of the epidemic and control the number of infected people, instead of spreading or increasing the number of infected people. In addition, the Ministry of Public Health has prepared protective equipment, patient beds, medical supplies, and medicines to prepare for the treatment of patients with coronavirus. However, from the aforementioned preventive measures that have been implemented since the beginning of 2020 until the end of 2020, a number of new infections are still being found. Recently, Thailand has experienced a third wave of COVID-19 outbreaks in April 2021. By analyzing the number of confirmed cases, it can be concluded that this cycle had more cases than the previous wave of infections, as shown in Figures 1 and 2. Figure 1 shows the number of daily COVID-19 cases. The graph indicates that the number of daily infections increased sharply since the beginning of April as compared to the number of infections from the previous wave. With the latest figures reported (reference as of 13 July 2021), the number of infected people stood at 8685. Figure 2 shows the total COVID-19 cases in Thailand from January 2020 to July 2021. The graph shows that the cumulative number of infections from the beginning of 2020 to the middle of 2021 increased and the level of this increase was significant in April 2021. Based on the statistics of the number of infected cases shown, we can conclude that past preventive measures such as proactive screening measures or even lockdown measures have not been very effective as a guideline for tackling the spread of COVID-19, as we can see that the number of infected people has continued to increase.

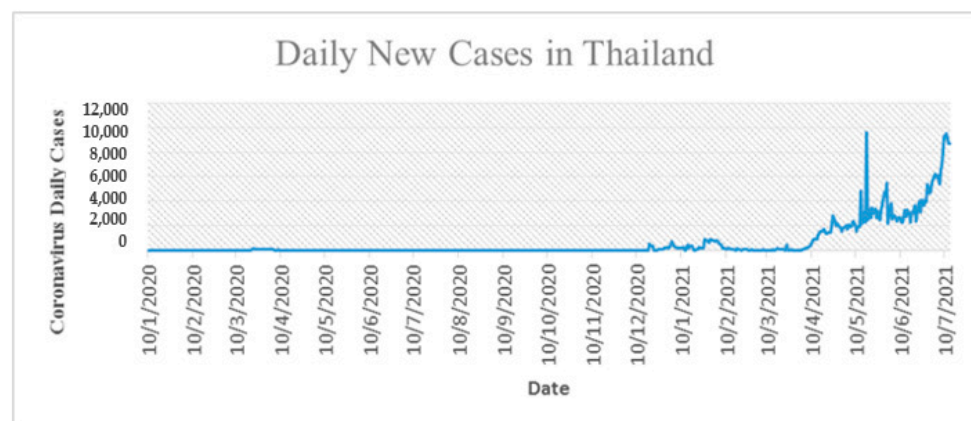

Figure 1. New daily cases in Thailand (source: <https://www.worldometers.info/coronavirus/country/thailand/> (accessed on 8 October 2021)).

Figure 2. Total coronavirus cases in Thailand (source: <https://www.worldometers.info/coronavirus/country/thailand/> (accessed on 8 October 2021)).

After a third wave of COVID-19 pandemic outbreaks in April 2021, we have been aware of the increasing number of infections and their tendency to increase steadily; as a result, Thailand had to try to find other ways to solve the COVID-19 epidemic more effectively. Therefore, since April 2021, Thailand has started implementing a vaccination policy by distributing to at-risk groups or to medical personnel first. The statistics of the number of people who have been vaccinated in Thailand and the percentage of people who have been vaccinated in Thailand are shown in Figures 3 and 4.

Figure 3. The number of people who received at least one dose of the COVID-19 vaccine (source: <https://www.worldometers.info/coronavirus/country/thailand/> (accessed on 8 October 2021)).

Figure 3 shows the number of Thai people who received at least one dose of the COVID-19 vaccine. This figure shows that Thailand is trying to push policies on the distribution of vaccines to the public thoroughly. This can be observed from the increasing number of people vaccinated in Thailand since March 2021 until now.

Figure 4 shows the share of Thai people who received at least one dose of the COVID-19 vaccine. This figure shows the increasing percentage of Thai people vaccinated in Thailand. The current population of Thailand is 70,015,933 as of Sunday, 26 September 2021, based on Worldometer's elaboration of the latest United Nations data (source: <https://www.worldometers.info/> (accessed on 8 October 2021)). A percentage of 22.73% of Thailand's population have been fully vaccinated against COVID-19 and 19.45% of Thailand's population have only partly been vaccinated against COVID-19 (source: <https://ourworldindata.org/> (accessed on 8 October 2021)).

Furthermore, Figure 5 also shows better signs that vaccinations are being distributed to all people with greater access to the COVID-19 vaccine and when compared with other Asian countries. Thailand has a higher level of vaccination distribution than other countries in Asia as well (see Figure 5). Thailand has the second highest number of vaccinated persons

among ASEAN-10 countries after Indonesia, followed by Malaysia, Vietnam, Philippines, Cambodia, Singapore, Myanmar, Laos, and Brunei.

Figure 4. The share of people who received at least one dose of the COVID-19 vaccine (source: <https://www.worldometers.info/coronavirus/country/thailand/> (accessed on 8 October 2021)).

Figure 5. The number of people who received at least one dose of the COVID-19 vaccine in ASEAN-10 (source: <https://www.worldometers.info/coronavirus/country/thailand/> (accessed on 8 October 2021)).

Thailand has issued a policy of vaccination to prevent COVID-19 due to the large number of infected people. Vaccination measures have begun to be implemented with the distribution of vaccinations to various provinces across the country. It is hoped that vaccination will reduce the number of infected people. However, from the daily reports of infected people, the number of new cases in Thailand has continued despite the fact that Thailand has had more COVID-19 vaccinations. Moreover, the death rate has continued to rise since the April outbreak (see Figure 6). Figure 6 shows the total coronavirus deaths in Thailand. From Figure 6, it can be seen that the mortality rate tended to increase day by day, even after vaccination.

Figure 6. Total coronavirus deaths in Thailand (source: <https://www.worldometers.info/coronavirus/country/thailand/> (accessed on 8 October 2021)).

Figure 7 shows the total confirmed COVID-19 cases per million people in ASEAN-10. By comparing the number of COVID-19 cases in ASEAN-10, as shown in Figure 7, Thailand still has more cases than Singapore, Brunei, Myanmar, Vietnam, Cambodia, and Laos, although Thailand has more people who have been vaccinated. Therefore, all the data statistics support the idea that although Thailand has continuously increased COVID-19 vaccinations, it still cannot bring the infection down to a level where new infections are undetectable, and not anytime soon. However, we have not seen a trend to achieving control of this wave of disease anytime soon; in other words, Thailand has not been able to detect new infections. The authors have therefore tried to find the right number of infections during the crisis period in order to try to reduce the economic impact that will occur to the country. The number obtained from this study will be the number of new cases that also contribute to the country's real economy with the GDP that can continue to circulate.

Figure 7. The total confirmed COVID-19 cases per million people in ASEAN-10 (source: <https://www.worldometers.info/coronavirus/country/thailand/> (accessed on 8 October 2021)).

Therefore, based on all data, it has been accepted in this study that the country will be unable to limit the number of infections to zero in the near future. Due to the fact that Thailand does not have any new cases, causing the number of new infections to stay at zero, it may not be able to achieve this in the near-term. Although Thailand has continuously been vaccinating people, at the same time, the country's economy cannot be disrupted by the number of infections being found each day. This has caused researchers to realize the importance of this issue in trying to keep the country's economy circulating despite the

number of infections found. This is something that the government should pay attention to because the country is not able to vaccinate everyone in the country at the moment, and the government cannot lock-down the whole country at the same time, because of the economic impact that will have. According to a study by [Hürtgen \(2020\)](#), it was stated that the “Great Lockdown” implemented in response to the COVID-19 pandemic led to a severe worldwide economic crisis. This demonstrates the opinion that limiting the number of infected people is the most appropriate method that can be carried out at this time to avoid the country’s lockdown policy. For that reason, the researchers intended to find the optimal number of COVID-19 cases in Thailand to maintain circulation of the country’s economy even though a number of people are still contracting infections.

In this study, we chose the model called dynamic stochastic general equilibrium (DSGE) with a Bayesian approach using modern macroeconomic theory to explain and predict co-movements of aggregate time series over the business cycle and to perform policy analysis. As the econometric analysis has to cope with several challenges, including potential model misspecification and identification problems, the Bayesian framework can address these challenges ([An and Schorfheide 2007](#)). This study is the first DSGE model-based Bayesian approach in analyzing the effects of COVID-19 infection to the Thai economy. Our contribution is to apply this method successively to an artificial dataset generated from a Bayesian DSGE model. We provided some evidence on the performance of Markov Chain Monte Carlo (MCMC) methods that have been applied to the Bayesian estimation of DSGE models. Moreover, we present the results about the response pattern of real GDP to the number of daily COVID-19 cases. The remaining parts of the paper are arranged as follows: the literature review is discussed in Section 2, Section 3 demonstrates the data and methodology, Section 4 presents the empirical results, and Section 5 finally describes the conclusions and policy recommendations.

2. Literature Review

There is much research that has studied the policy or the impact of policies used to deal with the COVID-19 pandemic, especially lockdown policy, e.g., [Ng \(2020\)](#), [Alvarez et al. \(2020\)](#), [Gonzalez-Eiras and Niepelt \(2020\)](#), and [Maliszewska et al. \(2020\)](#). [Maliszewska et al. \(2020\)](#) studied the potential impact of COVID-19 on gross domestic product and trade, using a general equilibrium model. They modeled the shock as an underutilization of labor and capital, an increase in international trade costs, a drop in travel services, and a redirection of demand away from activities that require proximity between people. A baseline global pandemic scenario saw gross domestic product falling below the benchmark around the world. The largest negative shock was the output of domestic services and traded tourist services. [Ng \(2020\)](#) studied macroeconomic analysis on the COVID-19 epidemic in the US and found that the lockdown policy alone was ineffective in controlling the epidemic. Broadening testing solely will accelerate the return to normal life as there are fewer infected people hanging around. However, as people do not internalize the social costs of returning to normal life, the epidemic could become even worse. Moreover, increasing medical capacity without any other measures only has temporary effects on reducing the death toll. [Alvarez et al. \(2020\)](#) studied the optimal lockdown policy in order to control the fatalities of a pandemic while minimizing the output costs of the lockdown by employing the SIR epidemiology model and a linear economy. The optimal policy prescribes a severe lockdown beginning two weeks after the outbreak and is gradually withdrawn after 3 months. Welfare under the optimal policy is higher; therefore, shortening the duration of the optimal lockdown is one of the considerations. [Gonzalez-Eiras and Niepelt \(2020\)](#) tried to determine formulas for the optimal lockdown intensity and duration. The optimal policy reflects the rate of time preference, epidemiological factors, the hazard rate of vaccine discovery, learning effects in the healthcare sector, and the severity of output losses due to a lockdown. COVID-19 shock triggers a reduction in economic activity by two thirds or approximately 9.5% of annual GDP.

The model called the dynamic stochastic general equilibrium (DSGE) model was chosen to be employed in various studies (Alaminos et al. 2020; Amiri et al. 2021), especially being used in the study of the current COVID-19 pandemic situation that the world is experiencing. The DSGE model is one of the most popular and interesting models for analyzing the COVID-19 situation and economic cycle. Examples of studies that are related to COVID-19 and economic cycles where the DSGE model has been used are Can et al. (2021), Hürtgen (2021), Bosca et al. (2021), and Hürtgen (2020). Can et al. (2021) explored the effectiveness of macroeconomic recovery policies in Turkey implemented by fiscal and monetary authorities against the COVID-19 pandemic. Consequently, a dynamic stochastic general equilibrium (DSGE) model was built. Stochastic simulations of the model revealed the propagation of COVID-19 shock, and the impacts of fiscal and monetary tools on the selected economic variables. The simulations indicated that direct fiscal measures were more effective in mitigating negative economic impacts of COVID-19. Hürtgen (2020, 2021) explored the response of the “Great Lockdown” to the COVID-19 pandemic. This policy has led to a severe worldwide economic crisis, while Hürtgen (2020) found that fiscal space contracted by 58.4% of national GDP for the five largest euro area countries. In a worst-case scenario, fiscal space was at 28.6% for Italy and 65.9% of national GDP for Germany. Moreover, Hürtgen (2021) found that the fiscal space contracted by 58.4% of national GDP on average. Bosca et al. (2021) analyzed the stabilizing macroeconomic effects of economic policies during the COVID-19 crisis in Spain by employing the DSGE model estimated for the Spanish economy. The empirical findings showed that the annual gross domestic product (GDP) fell by at least 7.6 points during the most severe part of the COVID-19 pandemic.

Furthermore, the DSGE model was extended into the DSGE model based on the Bayesian approach. There have been many studies that have reviewed Bayesian estimation and evaluation techniques that have been developed for empirical work with the DSGE model, e.g., An and Schorfheide (2007), Kim and Pagan (1995), and Canova (2007). The concept of using the DSGE model-based Bayesian approach was because the Bayesian framework could address the challenges such as potential model misspecification and identification problems, while the econometric analysis could not do so. The DSGE model-based Bayesian approach, which was extended from the original model of DSGE, was employed in various studies such as Zhang and Zhang (2020) and Nakhli et al. (2021). Zhang and Zhang (2020) investigated the economic and environmental effects of the carbon tax and carbon intensity target. The results indicate that both the carbon tax and carbon intensity target policies have a negative effect on China’s economy and environment. Moreover, Nakhli et al. (2021) analyzed the effects of sanctions and found that sanctions on the oil industry had a number of impacts, such as reducing the amount of foreign and government investment. Moreover, in the financial and exchange sectors, sanctions reduce the central bank’s foreign exchange reserve ratio, which slightly increases the exchange rate. As a result, nonoil exports increased and imports decreased. In the public sector, government oil revenues declined; however, consumption expenditures increased and investment expenditures declined due to projected inflation in the household sector. The conclusions from all previous studies indicated that the Bayesian DSGE model can be applied to all fields of analysis. This model demonstrates its usefulness for analysis in using macroeconomic data to analyze business cycles.

3. Research Methodology and Dataset

3.1. Methodology

3.1.1. Bayesian Structural Time Series (BSTS) Analysis for Nowcasting

The Bayesian structural time series model is shown in Equation (1) (Koduvely 2015; Jun 2019):

$$P(\theta|x) = \frac{P(x|\theta)P(\theta)}{P(x)} \quad (1)$$

where:

x is the observed data;
 θ is the parameter;
 $P(x|\theta)$ is the function of prior and likelihood;
 $P(\theta|x)$ is the function of posterior.

This model is updated by learning x given θ , which is a likelihood. The Gaussian distribution and the Bayesian regression model can be employed in order to set the prior. The model can be shown as in Equation (2) (Gelman and Shalizi 2013).

$$y = \beta_0 + \sum_{p=1}^p \beta_i x_i + e^* \quad (2)$$

where e is a Gaussian distribution with $(0, \sigma^2)$. In this application, inverse-chi square (Inv- x^2) is the determinant of the prior of σ^2 . This can be described as shown in Equation (3).

$$\sigma^2 \sim \text{Inv} - x^2(n - p, s^2) \quad (3)$$

where:

n is the data;
 p is the size of the parameter;
 s^2 is given by Equation (4).

$$s^2 = \frac{1}{n - p} (y - X\hat{\beta})^T (y - X\hat{\beta}) \quad (4)$$

The local linear trend is the first component of the BSTS model for nowcasting without behavioral data from Google Trends. The local linear trend can be defined by the two following formulas:

$$\mu_{t+1} = \mu_t + \delta_t + \eta_{\mu,t} \quad (5)$$

$$\delta_{t+1} = \delta_t + \eta_{\delta,t} \quad (6)$$

where:

$\eta_{\mu,t}$ is the normal distribution $N(0, \sigma_{\mu,t}^2)$;
 $\eta_{\delta,t}$ is the normal distribution $N(0, \sigma_{\delta,t}^2)$;
 μ_t is the trend value at time t ;
 δ_t is the expected increase in μ between time t and $t + 1$.

Thus, it can be implied as a slope at time t . On the other hand, the data from Google Trends are included in the model from the modification of Equation (2).

Thus, it starts with Equation (2) as

$$y = \beta_0 + \sum_{p=1}^p \beta_i x_i + e^*$$

When the data from Google Trends are included as

$$y_t = \mu_t + \beta^T x_t + \varepsilon_t \quad (7)$$

$$\mu_{t+1} = \mu_t + \delta_t + \eta_{0,t} \quad (8)$$

$$\delta_{t+1} = \delta_t + \eta_{1,t} \quad (9)$$

where $\beta^T x_t$ is the dimension of behavioral factors included into the structural time-series model.

3.1.2. DSGE Models

There are some pioneering studies on the Bayesian DSGE model, such as [An and Schorfheide \(2007\)](#), [Kim and Pagan \(1995\)](#), and the book by [Canova \(2007\)](#). The household, firm, and financial sectors can be considered in the economics model. Output is produced according to the Cobb–Douglas production function.

$$GDP_t = K_t^\alpha (A_t N_t)^{1-\alpha} \quad (10)$$

where:

K_t is the capital stock at the beginning of period (t);

N_t is the labor (input);

A_t is a technology.

The economics model is perturbed by technology and money stock processes. Technology is shown in Equation (11).

$$\ln(A_t) = \gamma + \ln A_t - 1 + \varepsilon_{A,t}; \varepsilon_{A,t} \sim N(0, \sigma_A^2) \quad (11)$$

Money stock (M_t) grows at rate $m_t = M_{t+1}/M_t$, which is defined by the central bank. This equation can be written as shown in Equation (12).

$$\ln m_t = (1 - \rho) \ln m^* + \rho \ln m_t - 1 + \varepsilon_{M,t}; \varepsilon_{M,t} \sim N(0, \sigma_M^2) \quad (12)$$

Equation (12) is a simple rule of monetary policy. First, at period t , M_t is the entire money stock of the economy, which inherits by household. P_t is the price level. In the standard CIA model, all decisions made rely on the changing of the money growth and technology. The D_t is the households' money that deposit at the bank with interest rate at rate $R_{H,t} - 1$.

The bank receives household deposits and a monetary injection (X_t) from the central bank, which it lends to the firm at rate $R_{F,t} - 1$. The firm hires labor from the household and pays wages ($W_t H_t$), which are borrowed from the financial institution. The cash balance of the household increases to $M_t - D_t + W_t H_t$. The consumption function is illustrated as in Equation (13).

$$\begin{aligned} & \max_{\{C_t, H_t, M_{t+1}, D_t\}} E_0 \left[\sum_{t=0}^{\infty} \beta_t [(1 - \phi) \ln C_t + \phi \ln(1 - H_t)] \right] \\ & s.t. P_t C_t \leq M_t - D_t + W_t H_t \\ & 0 \leq D_t \\ & M_t + 1 = (M_t - D_t + W_t H_t - P_t C_t) + R_{H,t} D_t + F_t B_t \end{aligned} \quad (13)$$

where:

$M_t - D_t + W_t H_t$ is the cash balance of the household;

F_t is the dividend of net cash inflow from firm to household;

B_t is the dividend of net cash inflow from bank to household;

C_t is the consumption;

H_t is the working hours;

D_t is the positive deposits.

Equation (14) is the financial equation.

$$\begin{aligned} & \max_{\{F_t, K_{t+1}, N_t, L_t\}} E_0 \left[\sum_{t=0}^{\infty} \beta^{t+1} \frac{F_t}{C_{t+1} P_{t+1}} \right] \\ & s.t. F_t \leq L_t + P_t \left[K_t^\alpha (A_t N_t)^{1-\alpha} - K_{t+1} + (1 - \delta) K_t \right] - W_t N_t - L_t R_{F,t} \\ & W_t N_t \leq L_t \end{aligned} \quad (14)$$

where:

K_{t+1} is the capital stock at the next period ($t + 1$);
 N_t is the demand of labor;
 F_t is the dividend;
 L_t is the loans.

Equation (15) is the trivial problem that is solved by the financial intermediary.

$$\begin{aligned} \max_{\{B_t, L_t, D_t\}} E_0 \left[\sum_{t=1}^{\infty} \beta^{t+1} \frac{B_t}{C_{t+1} P_{t+1}} \right] \\ \text{s.t. } B_t = D_t + R_{F,t} L_t - R_{H,t} D_t - L_t + X_t \\ L_t \leq X_t + D_t \end{aligned} \tag{15}$$

where:

X_t is the monetary injection when $X_t = M_{t+1} - M_t$;
 H_t is the condition of market clearing for the market of labor when $H_t = N_t$;
 $P_t C_t$ is the condition of market clearing for the market of money when $P_t C_t = M_t + X_t$;
 $C_t + (K_t + 1 - (1 - \delta)K_t)$ is the condition for the goods market when
 $C_t + (K_t + 1 - (1 - \delta)K_t) = K_t^\alpha (A_t H_t)^{1-\alpha}$;
 $R_{F,t} = R_{H,t}$ is the equilibrium point.

As we assume that the household makes the decision (D_t) of deposit before observing the shock from monetary growth ($\varepsilon_{M,t}$) and technology ($\varepsilon_{A,t}$), after the household is observed, the household chooses the consumption (C_t), the labor supply (H_t), and the deposit of the next period (D_{t+1}). In the case after the change of money growth rates, the household cannot revise its deposit decision. Thus, the nominal interest rate falls as the firm absorbs the additional cash. [Christiano and Eichenbaum \(1992\)](#) stated that the household holds cash in order to make the liquidity persistently. The portfolio management cost is introduced, as shown in Equation (16).

$$\tilde{P}_t = \alpha_1 \left[\exp \left\{ \alpha_2 \left[\frac{Q_t}{Q_{t-1}} - m^* \right] \right\} + \exp \left\{ -\alpha_2 \left[\frac{Q_t}{Q_{t-1}} - m^* \right] \right\} - 2 \right] \tag{16}$$

where Q_t is the household's cash holding when $Q_t = M_t - D_t$. Equation (7) can reduce the time available for leisure. Thus, the household's problem is shown in Equation (17).

$$\begin{aligned} \max_{\{C_t, H_t, M_{t+1}, Q_{t+1}\}} E_0 \left[\sum_{t=1}^{\infty} \beta^t [(1 - \phi)] \ln C_t + \phi \ln (1 - H_t - \tilde{P}_t) \right] \\ \text{s.t. } P_t C_t \leq Q_t + W_t H_t \\ Q_t \leq M_t \\ M_{t+1} = (Q_t + W_t H_t - P_t C_t) + R_{H,t} (M_t - Q_t) + F_t + B_t \end{aligned} \tag{17}$$

The optimality conditions can be derived in order to maximize the problems. The real variables are detrended by the productivity (A_t). The price level is detrended by $\frac{M_t}{A_t}$. X_t, Q_t and D_t are detrended by M_t . This illustrates that the system in the detrended variables has a deterministic steady state and can be log-linearized around it, eliminating the unstable roots according to the algorithm in [Sims \(1995\)](#), which provide the solution to a linear rational expectation system.

Let y_t be a vector of observed variables. The log-linearized DSGE model yields state-space representations for y_i .

$$y_t = \Xi_0 + \Xi_{1S_t} + \Xi_{*\varepsilon_t} \tag{18}$$

$$S_t = \Psi_{1S_t} - 1 + \Psi_{*\varepsilon_t}, \varepsilon_t \sim iidN(0, \sum \varepsilon) \tag{19}$$

where:

Ξ_i, Ψ_i are the parameters of the structural DSGE model:

$$\varepsilon_t = [\varepsilon_{A,t}, \varepsilon_{M,t}]$$

Σ_ε is the diagonal matrix with elements σ_A^2 and σ_M^2 .

S_t is the vector of percentage deviations of detrended model variables from the steady-state.

$$\theta = [\alpha, \beta, \gamma, m^*, \rho, \phi, \delta, \sigma_A, \sigma_M, \alpha_1, \alpha_2]' \tag{20}$$

The joint probability for the data $Y_T = [y_1, \dots, y_T]'$ can be derived from the DSGE model.

3.1.3. Bayesian DSGE Model

We assume that M_1 is the CIA (cash-in-advance) model and M_2 is the PAC model. $\theta_1 \in \Theta_1$ is the parameter vector of the CIA model. $\theta_2 \in \Theta_2$ is the parameter vector of the PAC model. The Bayesian approach was adopted and placed the probability on models and their parameters.

Let $p(Y_T|\theta_1, M_1)$ be the likelihood function for the CIA model:

$p(\theta_1|M_1)$ is the prior for parameters;

$p(Y_T|\theta_2, M_2)$ is the likelihood function for the PAC model;

$p(\theta_2|M_2)$ is the prior for parameters.

Thus, we can conclude that $p(Y_T|\theta_i, M_i)$ is the likelihood function for model i . $p(\theta_i|M_i)$ is the prior for parameters in model i .

For model evaluation, we follow four steps as the following;

Step 1: Calculate posterior distributions $[p(\theta_i|Y_T, M_i)]$ for parameters of model $[\theta_{(i)}]$ and calculate posterior probability.

$$\pi_{i,T} = \frac{\pi_{i,0}p(Y_T|M_i)}{\sum_{i=0}^2 \pi_{i,0}p(Y_T|M_i)} \tag{21}$$

where $p(Y_T|M_i)$ is the marginal density of data:

$$p(Y_T|M_i) = \int p(Y_T|\theta_{(i)}, M_i)p(\theta_{(i)}|M_i)d\theta_{(i)} \tag{22}$$

Step 2: The characteristics of population (φ) are a function $[f_i(\theta_{(i)})]$ of the parameter $\theta_{(i)}$. The posterior for φ conditional on model M_i can be divided based on the posterior distribution of $\theta_{(i)}$. $p(\varphi|Y_T, M_i)$ is the notation of the posterior.

The overall posterior of φ is shown in Equation (23).

$$p(\varphi|Y_T) = \sum_{i=0}^2 \pi_{i,T}p(\varphi|Y_T, M_i) \tag{23}$$

where $p(\varphi|Y_T, M_i)$ is the weights of the density.

$p(\varphi|Y_T, M_i)$ can be determined by the posterior probabilities $\pi_{i,T}$.

Step 3: The ability of the DSGE model can be assessed by employing the loss function $(L(\varphi, \hat{\varphi}))$. We assess the DSGE model to replicate patterns of co-movement among key macroeconomic variables and impulse responses to structural shocks. The loss function penalizes deviations in DSGE model predictions $\hat{\varphi}$ from population characteristics φ .

The prediction from the DSGE model M_i is obtained as follows:

The optimal predictor is shown in Equation (24).

$$\hat{\varphi}_i = \operatorname{argmin}_{\tilde{\varphi} \in R^m} \int L(\varphi, \tilde{\varphi})p(\varphi|Y_T, M_i)d\varphi \tag{24}$$

where $p(\varphi|Y_T)$ is the overall posterior distribution.

The two DSGE models are determined according to the expected loss (risk) of $\tilde{\varphi}_i$ under the overall posterior distribution.

The posterior risk is shown in Equation (25).

$$R(\tilde{\varphi}_i|Y_T) = \int L(\varphi, \tilde{\varphi}_i)p(\varphi|Y_T)d\varphi \quad (25)$$

The posterior risk can measure of how well model M_i predicts the population characteristics φ . We can select the DSGE model M_i that minimizes $R(\tilde{\varphi}_i|Y_T)$.

Step 4: We solve the minimization problem in order to derive loss function parameter estimates $\hat{\theta}_{l,i}$ as φ is a function $[f_i(\cdot)]$ of the parameters $\theta_{(i)}$. This is illustrated as shown in Equation (26).

$$\hat{\theta}_{l,i} = \operatorname{argmin}_{\theta_{(i)} \in \Theta_{(i)}} R\left(f_i\left(\theta_{(i)}\right)|Y_T\right) \quad (26)$$

These estimates can find the structural parameter estimates that achieve the best fit of model M_i in a particular dimension.

3.2. Dataset

According to this research, we attempt to forecast the optimal numbers of COVID-19 infection at the level for maintaining the economic circular flows in Thailand for avoiding lockdown policy. Thus, the dataset for this research focused on the macroeconomic data (2020–2021) and new cases of COVID-19 infection from 2020 to 2021 (the starting point of the COVID-19 pandemic of Thailand until the present time: source: <https://ddc.moph.go.th/viralpneumonia/index.php> (accessed on 8 October 2021)).

4. Empirical Results

4.1. Data Visualization and Data Description

Figure 8 shows the data visualization for real GDP and the number of COVID-19 infection cases from Q1 2020 to Q1 2021. The original quarterly dataset consists of five observations.

Table 1 shows the statistical data for real GDP and the number of COVID-19 infection cases. The minimum and maximum of the datasets of real GDP are 95,315 and 105,349, respectively. The mean of the real GDP dataset is 101,410, while the mean of the number of COVID-19 infection cases is 5688. The minimum and maximum of the dataset of the number of COVID-19 infection cases are 486 and 20,656, respectively.

Figure 8. Data visualization (source: author).

Table 1. Data statistics description (source: calculated).

	Real GDP (mn USD)	Infected Number (Persons)
Min.	95,315	486
1st Qu.	101,356	1516
Median	102,424	2170
Mean	101,410	5688
3rd Qu.	102,605	3613
Max.	105,349	20,656

4.2. Data Simulation by Bayesian Regression Model

4.2.1. Observations = 100 (Quaternary Data)

Figure 9 shows the simulated dataset for real GDP and the number of COVID-19 infection cases. In this case, we simulated the dataset equaling 100 observations ($n = 100$).

Table 2 shows the statistical dataset ($n = 100$) after simulating for real GDP and the number of COVID-19 infection cases. The minimum and maximum of the dataset of real GDP are 100,658 and 106,440, respectively. The median of the real GDP dataset is 103,981, while the median of the number of COVID-19 infection cases is 8369. The minimum and maximum of the datasets of the number of COVID-19 infection cases are 3936 and 14,071, respectively.

**Figure 9.** The data simulation $n = 100$ (source: author).**Table 2.** Data statistics description (source: calculated).

	Real GDP (mn USD)	Infected Number (Persons)
Min.	100,658	3936
1st Qu.	103,271	7080
Median	103,981	8369
Mean	103,955	8430
3rd Qu.	104,942	9845
Max.	106,440	14,071

4.2.2. Observations = 250 (Quaternary Data)

Figure 10 shows the simulated dataset for real GDP and the number of COVID-19 infection cases. In this case, we simulated a dataset equaling 250 observations ($n = 250$).

Table 3 shows the statistical dataset ($n = 250$) after simulating for real GDP and the number of COVID-19 infection cases. The minimum and maximum of the dataset of real GDP are 102,286 and 120,152, respectively. The median of the real GDP dataset is 110,920, while the median of the number of COVID-19 infection cases is 16,146. The minimum and maximum of the dataset of the number of COVID-19 infection cases are 1448 and 24,751, respectively.

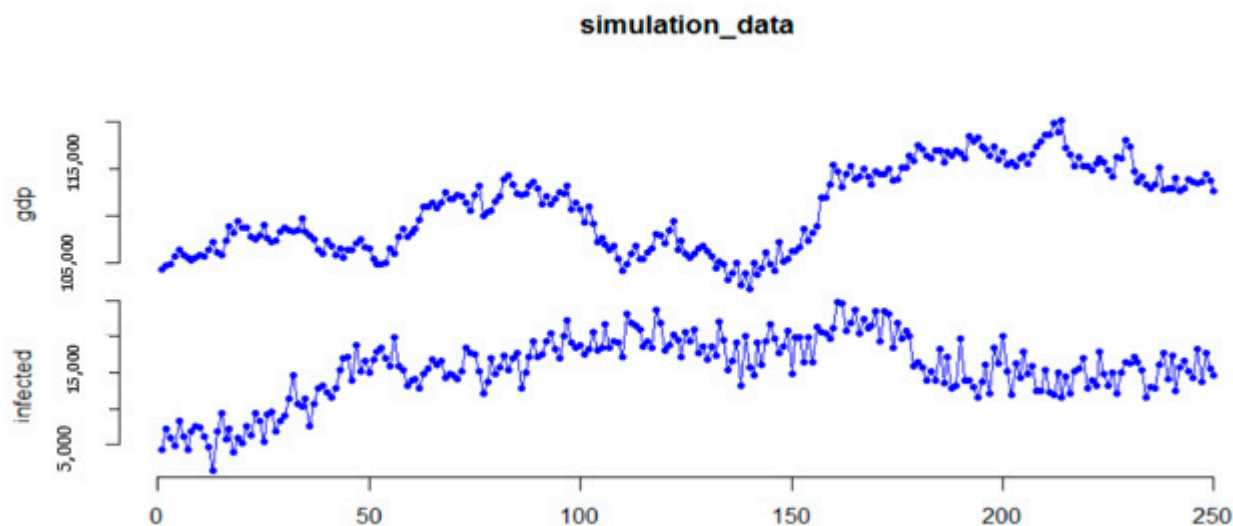

Figure 10. The data simulation $n = 250$ (source: author).

Table 3. Data statistics description (source: calculated).

	Real GDP (mn USD)	Infected Number (Persons)
Min.	102,286	1448
1st Qu.	106,618	13,178
Median	110,920	16,146
Mean	110,750	15,621
3rd Qu.	114,444	18,651
Max.	120,152	24,751

4.2.3. Observations = 500 (Quaternary Data)

Figure 11 shows the simulated dataset for real GDP and the number of COVID-19 infection cases. In this case, we simulated a dataset equaling 500 observations ($n = 500$).

Table 4 shows the statistical dataset ($n = 500$) after simulating for real GDP and the number of COVID-19 infection cases. The minimum and maximum of the dataset of real GDP are 100,978 and 166,756, respectively. The median of the real GDP dataset is 121,594, while the median of the number of COVID-19 infection cases is 32,161. The minimum and maximum of the dataset of the number of COVID-19 infection cases are 3623 and 66,321, respectively.

4.3. Regression Kink Model

In this case, after we simulated data equal to 100 observations, the kink model could be used. The turning point is 8588.128 (as shown in Figure 12 and Table A2 in Appendix A). From this number, it can be concluded that during each quarter of the COVID-19 pandemic outbreak, the study found that the optimal number of COVID-19 cases should not exceed 8588.128 cases per quarter. In addition, 5571.63 and 9972.63 are the lower- and upper-bound, respectively. Therefore, the number of infections can range from 5571.63 to 9972.63, which

is considered the number of infections that will keep the country’s economy circulating (see more detail in Appendix A).

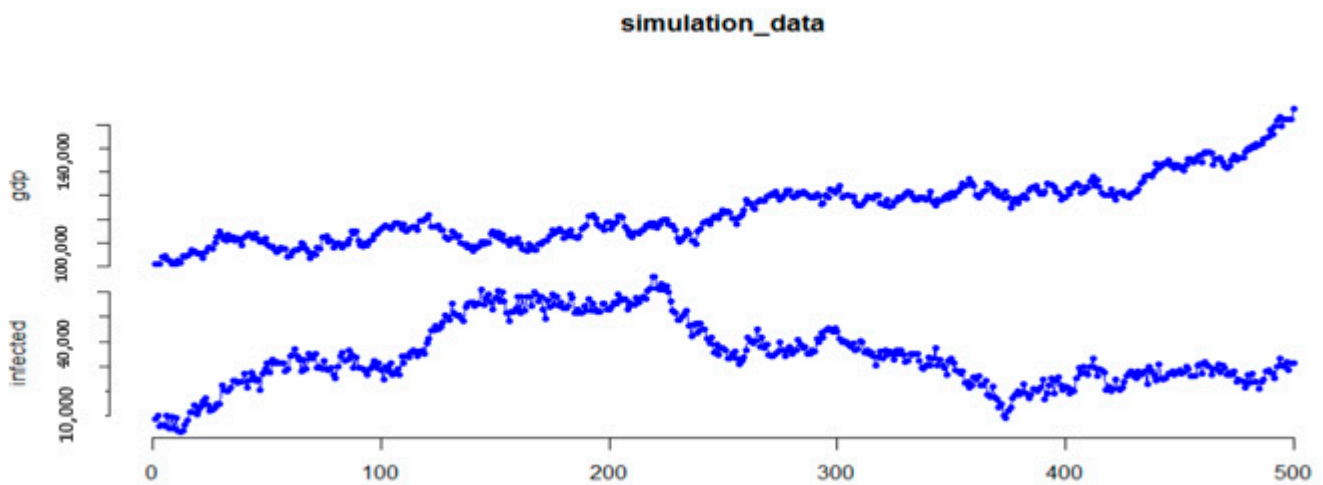

Figure 11. The data simulation $n = 500$ (Source: author).

Table 4. Data statistics description (source: calculated).

	Real GDP (mn USD)	Infected Number (Persons)
Min.	100,978	3623
1st Qu.	112,223	26,260
Median	121,594	32,161
Mean	123,446	34,551
3rd Qu.	131,142	43,954
Max.	166,756	66,321

Figure 12. The relationship between the number of COVID-19 infection cases and GDP in Thailand when $n = 100$ (source: author).

In this case, after we simulated data equal to 250 observations, the kink model could be used. The turning point is 12,365.55 (as shown in Figure 13 and Table A4 in Appendix A). Figure 13 shows the decline in GDP levels after passing the turning kink point. It can be concluded that if the number of infected people is more than 12,365.55 cases per quar-

ter, the country's GDP tends to decrease significantly. Therefore, the number of such infections cannot keep the country's economy circulating in the future (see more detail in Appendix A).

Figure 13. The relationship between number of COVID-19 infection cases and GDP in Thailand when $n = 250$ (source: author).

In this case, after we simulated data equal to 500 observations, the kink model could be used. The turning point is 22,843.47 (as shown in Figure 14 and Table A6 in Appendix A). Figure 14 shows the decline in GDP levels after passing the turning kink point. It can be concluded that if the number of infected people is more than 22,843.47 cases per quarter, the country's GDP tends to decrease significantly. Therefore, the number of such infections cannot keep the country's economy circulating in the future (see more detail Appendix A).

Figure 14. The relationship between number of COVID-19 infection cases and GDP in Thailand when $n = 500$ (source: author).

4.4. The Empirical Results of Bayesian DSGE Model

The result can be obtained that the number of infections is not more than 8600 per quarter or, on average, 3000 per month. Then, we predicted Q4 of 2021 to Q4 of 2024 (13 quarters) as the next period of time by employing the Bayesian DSGE Model.

In addition, where gp_obs is inflation (%) and gy_obs is GDP growth rate (%), they were predicted by the Bayesian DSGE model under the condition based on the optimal numbers of COVID-19 infection to maintain the economic circular flows of Thailand. The results show that the prediction from Q4 of 2021 to Q4 of 2024 (13 quarters), as shown in Figure 15, indicates that the inflation is not more than 2% and the GDP growth rate is not more than 3.5% (see more detail in Appendix A).

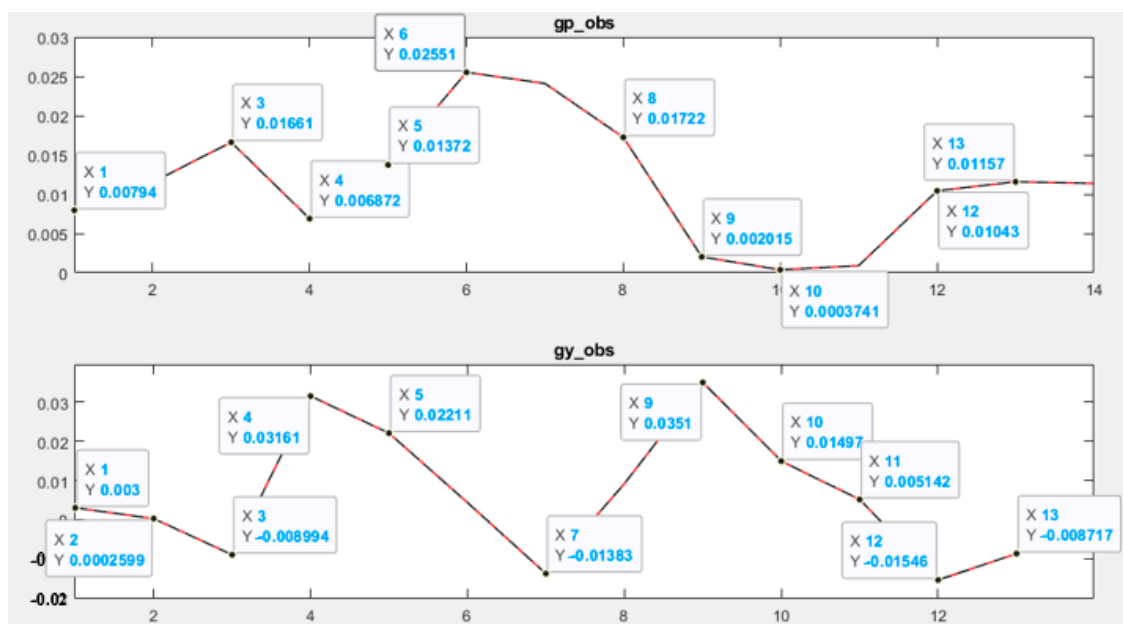

Figure 15. The prediction in the next 13 quarters in the future.

5. Conclusions, Discussions, and Policy Recommendations

We can answer the question, “At what number of COVID-19 cases could we still keep the country’s economy circulating?” based on the results of this study. The optimal number of new infections of COVID-19 cases that can maintain the circulation of the economy is 8588 people per quarter or approximately 3000 people per month. In this study, we tried to avoid the use of lockdown policies, but, unfortunately, we cannot immediately reduce the number of infected people to zero in the near future. Thus, this led us to deem this number (8588) from the result of this study acceptable. After that, we used this information to analyze the Bayesian DSGE model in order to show the trends of the household sector, manufacturing sector, and financial sector. The empirical results showed that the inflation was not more than 2% and the GDP growth rate was not more than 3.5%. According to policy recommendations, the results of this study showed that if Thailand wants to keep its economy circulating, the country must try to limit/control the number of COVID-19 cases to no more than 8588 people per quarter, or on average, should not exceed 3000 people per month. However, if the number of new daily COVID-19 cases exceeds this number, the country’s GDP will drop significantly.

The findings from this study offer important lessons for policymakers, as the government considers how policies should develop over the recovery phase of this crisis. Based on current data in July 2021, daily reports of new infections are still high with more than 10,000 new infections reported. Therefore, it can be concluded that in dealing with the COVID-19 pandemic, the implementation of the policy must be clearly more stringent than the previous time. There must be other policies rather than lockdowns as we have already seen that lockdowns alone, as Thailand has, cannot stop the spread of COVID-19. Expedited policies, including the vaccination policy for Thai people, should be accelerated in order to stop the infection and reduce the number of new infections every day. By vaccinating, vaccination should be allocated easily and be undisputedly accessible to people in all occupations. If both the public and private sectors in Thailand can act quickly and efficiently, the number of new cases of new infections in the country will be reduced in the near future. On the other hand, if Thailand fails to act effectively, the country’s economy may become uncirculated as measures will not be effectively implemented for the ultimate goal of reducing the number of new daily COVID-19 cases. Therefore, the results of this study can be used as a guideline during the time when Thailand is accelerating vaccination but may not be 100% by knowing the number of infected people that make the economy

still circulate. This is another way to manage and deal with the spread of COVID-19 in the future.

This study has some limitations that can be used as a future study guide because the study only focused on the number of COVID-19 cases that induced changes in real GDP. This study is a pioneer study as it is still too early to make an informed assessment of the full impact of the pandemic, especially about information of vaccination. Due to the study period of this work, we started from the beginning of the first wave of the epidemic, which was in early 2020. At that time, Thailand had not adopted a vaccination policy yet. In a future study, the vaccination policy can be employed to explore the optimal number of COVID-19 cases after everyone becomes vaccinated. The eventual optimal number of COVID-19 cases may be different, but it does convey the likely alternative of COVID-19 pandemic management apart from the lockdown policy in order to keep the economy circulating. Therefore, future studies should take other factors into account to make the number of infected people more flexible; for example, if we consider the number of vaccinations in the country, it may help increase the number obtained more than the result this time. However, due to this study, we used data since the beginning of the COVID-19 epidemic, and at that time, there were no vaccinations in Thailand. This makes this research a framework for only looking at the impact of the number of new infections on real GDP. Furthermore, we can try to consider extending the model with an indicator of hospitalized patients with COVID-19 to the future.
